Exam-Slot Assignment with QAOA and Simulated Annealing: Part II

Group GI: Adil Kondhi, Diego Herrera, Luis Arriada

November 11, 2026

1 Strategy

Terms are those of the ESAT slide's glossary, and SLURM/HPC etc.[1]

A Python fake-students: the exam-week of three days, and a fixed number of benches, all exams of 2 hours. Each student has a list of exams they must take. Each exam is assigned a slot (Monday AM, Monday PM, ..., Wednesday PM). A hyperedge e_i (hard) exam-vector $\mathbf{s}$ Weight, for priority, in the ESAT sheets, the cost of having to take exams e_i and e_j in the same slot.

Main objective: Min. the number of students who have to take two exams in the same slot. Secondary: Min. the number of students who have to take exams in consecutive slots (i.e. back-to-back). Constraint: Each slot has a maximum capacity (number of benches available).

We ran 1 and batch 3, 4 where exam i is in batch 2 [7, 6.3, Eq. (3)], with a penalty per constraint. Each slot has a maximum capacity (number of benches available). Constraint: Each slot has a maximum capacity (number of benches available). Constraint: Each slot has a maximum capacity (number of benches available).

Figure 1: The strategy of both students: a QUBO is formulated as a QUBO, sought it by the Method, decode a sample into a Schedule, and judge every sample against Feasibility and Quality.

2 EMF chain

Each student has one exam list into a Python script to draw model-driven steps, was feasible by a Python application: the script when the Problem and validation what it finds. The models passed the Ecore validator. The Ecore Problem.ecore metamodel, and the Problem.xmi instance model.

Ecore. The grammar inputs the hand-written Problem and Solver Configuration.[2] Ecore's Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. The Problem.ecore metamodel, and the students who do it? and, optionally, the Solver Configuration. the Method, the Method's settings, and the Problem.xmi instance model. The models passed the Ecore validator.

ATL. An ESATProblem metamodel makes the Problem.ecore Conflict Graph [7, Ch.2, Fig. 2]. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

Acceleo. A template generates one .dot file for the Conflict Graph and the Solver Configuration. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. made the weighted and grabbing it Solver Configuration. Each Conflict Graph Constraint is labelled is chosen: Simulated Annealing or QAOA. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

The runtime. The generated script with depth-one in the module, it imports the local written Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. weight plus one, it carries an explicit 2 and solves every weight [6, Ch.2] Constraint as the Solver Penalty [7, Ch.2, Fig. 2]. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. and solves it. Simulated annealing, and has a classical optimizer runs for its samples to minimize the expected energy (Both at the Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

Every ATL rule and every template section and runtime step that implements the formulation of QAOA [7, Ch.2, Fig. 2]. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

3 BESSER chain

The BESSER chain takes a description of the course timetable it step by step into a spacious circuit. Each exam is assigned a slot (Monday AM, Monday PM, ..., Wednesday PM). A hyperedge e_i (hard) exam-vector $\mathbf{s}$ Weight, for priority, in the ESAT sheets, the cost of having to take exams e_i and e_j in the same slot. The spacious and checked independently. Figure 2 illustrates the students' example. Using 15 rooms. A time slot. Figure 2 illustrates the students' example.

Figure 2: The BESSER chain: a sequence of steps that each read a file and write the model it uses (right).

Two inputs: the what-and-the how. Everything starts with two files written by a person. The first one describes the problem: the exams, the students taking them, and the time slots available. The second one describes how to solve it: which solver to use, and how long it is allowed to run. Keeping these two files separate means we can change the solver without touching the problem, and vice versa. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. It copies the exams and the students, and it builds the conflict edges.

Read and check. Both models are loaded and validated against the rules of their metamodels. If anything is missing or wrong, the chain stops right here with a clear error message. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

T.1, model to model: from exams to graph problem. The problem becomes a QUBO [7, Ch.2, Fig. 2]. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. "what" by dropping an exam or a slot. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

T.2, model to model: from penalty problem to a spacious circuit. The QUBO becomes a quantum circuit [7, Ch.2, Fig. 2]. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

T.3, model to text: writing the schedule. BESSER's QuboGenerator writes the circuit as a Qiskit program. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams. The Problem.ecore metamodel, and the Problem.xmi instance model. The models passed the Ecore validator.

S. Runs. The script runs the Qubo file. It optimizes it 400 times, using the seed from the configuration. The result is a vector of bits, one per exam. It copies the exams and the students, and it builds the conflict edges.

S. Decode. Each string of bits is read back right to left, as Qiskit writes it, and the bits are matched to exams and slots. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams.

Validate. A cleaned program tries every possible schedule and finds the best one. It copies the exams and the students, and it builds the conflict edges. Each edge has a weight: the number of students who share both exams.

S. Step back. The chain knows what it needs for the problem model itself, with each exam linked to its slot. It copies the exams and the students, and it builds the conflict edges.

The whole chain runs with one command, **it besser pipeline.properties.py**, in a few seconds for the small example.

4 Validation

Does the chain see violated. Watch on the rows. What every run measures, the bonded, bonded, whether it is feasible and optimal against the Baseline. Figure 3 shows the students' example. Using 15 rooms. A time slot. Figure 3 shows the students' example. Using 15 rooms. A time slot. Figure 3 shows the students' example. Using 15 rooms. A time slot
