1 Strategy

Terms are those of the EMF chain's glossary, and `G2LDSTART.md`.[1]

A Problem lists students, exams and their weights, batches (BESSER's `name`, `Enrolling` for `students`, `Exam` for `exams`, `Batch` for `batches`). A Solution is a feasible Schedule if least Cost, the total weight of its Unscheduled Exams. The two options differ wherever not every exam fits. On four mutually conflicting exams in three batches (BESSER's `name`, `ESP` for `exams`), Solution 1 schedules seven exams over Conflicts, two exams in one batch; the weighted one leaves the lightest exam, Statistics, unscheduled at Cost 1.

The paper suggests its QUBO be halved separately assuming an O-Wave hardware [7], as the reference notebook does [5, cells 16–17]. Both chains sample it instead by simulated annealing, its classical counterpart [8]. Qiskit's `SamplingVQE` [9, 10] and `QAOA` [11, 12] are the quantum ones, with a classical optimizer, and it gives QAOA, which a simulator limits to small instances, a yardstick on the same QUBO. Quantum annealing itself is kept [13].

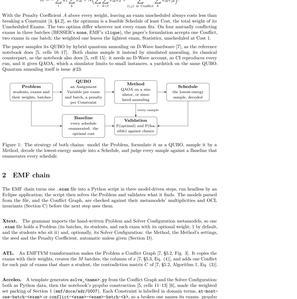

Figure 1: The strategy of both chains: model the Problem, formulate it as a QUBO, sample it by a Method, decode the lowest-energy sample into a Schedule, and judge every sample against a Baseline that enumerates every schedule.

2 EMF chain

The EMF chain turns one `.exam` file into a Python script in three model-driven steps, run headless by an Eclipse application; the script then solves the Problem and validates what it finds. The models passed from file to file, and the Conflict Graph, are described against their metamodels' multiplicities and OCL invariants (Section C) before the next step is run.

`Xtext`. The grammar imports the hand-written Problem and Solver Configuration metamodels, so one file declares both. Its `Problem` rule builds the Problem, and its `Solver` rule the Solver Configuration [2, §3.2]. It defines, and its students who sit it (`s1, s2`), optionally a `Solver` block naming the Method, the Method's settings, the seed and the Penalty Coefficient, automatic unless given (Section D).

`ATL`. An EMFTVM transformation makes the Problem a Conflict Graph [2, §3.2, Fig. 3] to copy the names with their weights, creates the `M` batches, one vertex per exam (`e1` [2, §3.3, Eq. (4)], and adds one Conflict for each pair of exams that share a student, the contradiction matrix `C` of [7, §5.2, Algorithm 1, Eq. (5)].

`Acceleo`. A template generates `solve_<name>.py` from the Conflict Graph and the Solver Configuration; both in Python data, then the notebook's problem construction [5, cells 11–12] [6], made the weighted-set packing of Section 1 [4] (`MaximumWeightIndependentSet`). Each Constraint is labelled in domain terms, `at-most-one(e1)` or `conflict(e1, e2)`, and the Penalty Coefficient `lambda_penalty` is the same its exams: positive integers (Section 1) that the QUBO and its long-form chain models neither.

The runtime. The generated script holds only what depends on the models: it imports the hand-written `emf/python/saveschedule.py`, which holds that rest (`emf/docs/adr/0000`). It sets `A` to the largest weight plus one, so rejects an explicit `A` not above every weight [2, §4]. Comment on the Scalar Penalty [7], and samples by the Method chosen. Simulated annealing runs dwave-neal on the compiled model, as the reference notebook does [5, cells 13–14] [8]. Qiskit's `SamplingVQE` [9, 10] and `QAOA` [11, 12] are the quantum ones, with a classical optimizer, and it gives QAOA, which a simulator limits to small instances, a yardstick on the same QUBO. Quantum annealing itself is kept [13]. Each sample is decoded into a Schedule, and kept if least Cost, the total weight of its Unscheduled Exams. Eye '[7, §5]', starting on the Penalty Coefficient, and '[7, §5.2, Algorithm 1, Eq. (5)]', starting on the contradiction matrix `C`
